Sarcopenia is defined as decreased muscle mass, muscle strength and physical performance. In geriatric patients, secondary sarcopenia may also develop due to underlying diseases in addition to the known primary sarcopenia. Computed tomography and magnetic resonance imaging are the gold standard to calculate skeletal muscle index in the diagnosis of sarcopenia. The diagnostic approach is easier in mobilized, outpatient and hospitalized patient. However, it is difficult to perform a gold standard computed tomography and magnetic resonance imaging for the diagnosis of sarcopenia and evaluate muscle strength and physical performance in patients who cannot be mobilized and stay in the intensive care unit. In this case report, we aimed to present the case in order to raise the awareness of clinicians considering the difficulty of application of diagnostic criteria of secondary sarcopenia in the course of prolonged intensive care unit hospitalization and difficulty of performing computed tomography and the lack of consensus on prevention and treatment of sarcopenia.

INTRODUCTION
Sarcopenia (decreased muscle mass and function) is characterized by cachexia, negative protein and energy balance, multi-organ syndrome, anorexia and decreased physical function (1). Sarcopenia was first described by Rosenberg in 1989 to draw attention to geriatric syndromes associated with decreased muscle mass with aging (2). The prevalence of sarcopenia generally ranges between 6-22% over the age of 65 years (3). It was first defined as primary sarcopenia characterized by decreased muscle mass in the elderly. Then, secondary sarcopenia, which is defined by three main pathogenic mechanisms (inflammatory activity, malnutrition and physical activity disorder), was described. Despite the widely used definition of primary sarcopenia, clinical trials for secondary sarcopenia are still insufficient (4). In particular, there are studies conducted on chronic diseases or in certain hospitalized groups. Although computed tomography (CT) and magnetic resonance imaging (MRI) are the gold standard in the diagnosis of sarcopenia, it is a difficult diagnostic procedure due to high cost and difficulty in clinical practice. Instead, dual-energy X-ray absorptiometry (DXA) and bioelectrical impedance analysis (BIA) are more easily applicable for diagnostic purposes (5). There is little awareness about the prognostic value of sarcopenia in patients with surgery, trauma and cancer, not only in elderly patients who are in intensive care unit (ICU) (6). In this article, we aimed to present a 65-year-old man with chronic lymphocytic leukemia (CLL) in remission who was hospitalized in the ICU for a long time period and diagnosed of sarcopenia by using CT evaluation. As a result, this case would draw attention to the development of secondary sarcopenia in ICU.

CASE
A 65-year-old male patient in remission of CLL for the last 1 year was admitted to the emergency department due to fever (39°C) and respiratory distress. His physical examination revealed bilateral rales, blurred consciousness, and drowsiness. Additionally, the Glasgow Coma Scale score was 4. Heart rate was 106/minute, respiratory rate was 48/minute, and oxygen saturation was 84% in room air. The patient was intubated due to respiratory failure. The blood pressure was 80/60 mmHg. Therefore, he was immediately treated with serum saline infusion. Subsequently, appropriate intravenous fluid administration and inotropic treatment were started. Furthermore, bilateral infiltration was detected on chest X-ray examination. Respiratory acidosis was detected in blood gas examination. He had normal liver and kidney functions. Leukopenia (506 cells/mm$^3$) and increased C-reactive protein (CRP) (342 mg/L) (our hospital reference levels: 0-5 mg/L) were identified. Eventually, he was transferred to the ICU with pre-diagnosis of pneumonia, sepsis and CLL relapse. Cranial CT scan was performed due to lethargy and confusion, and relieved normal findings. After admission to ICU, whole body fluid cultures were obtained, and then initial empirical intravenous (IV) antibiotics (ceftriaxone, vancomycin, and acyclovir) were started. Streptococcus pneumoniae susceptible to ceftriaxone was yielded in both cerebrospinal fluid and blood culture. Vancomycin and acyclovir treatments were discontinued after culture results. Ceftriaxone treatment was continued until negative control cultures. In hematological evaluation, CCL relapse was not considered in peripheral smear and bone marrow examination. The patient was extubated on the 19th day of hospitalization and started full enteral nutrition on the 25th day. The patient's calorie intake was regulated as 20–25 kcal/kg/day and protein intake was regulated to have 1.5 g/kg body (7). On the 26th day of hospitalization, the patient had fever (39.3°C), respiratory distress, lethargy, bilateral rales, respiratory acidosis, leukocytosis (22,400 cells/mm$^3$) and CRP: 285 mg/L which were indicated sepsis and pneumonia. Therefore, respiratory support was initiated with mechanical ventilator (MV). Subsequently, Acinetobacter baumannii was detected in the blood culture, and colistin was administered for 14 days.
for nosocomial pneumonia and sepsis. Respiratory physiotherapy was started and continued during hospitalization. In the follow-up, tracheostomy was applied because of extubation failure, and percutaneous endoscopic gastrostomy (PEG) was applied to maintain his nutrition.

On the 53rd day of hospitalization, sarcopenia was suspected because of failure in weaning from MV, low body mass index (17.4 kg/m², cut-off <20 kg/m²), low muscle mass, low muscle strength and low physical performance. Subsequently, CT, which was recognized the gold standard diagnostic method and the first of three diagnostic criteria for sarcopenia, was used to evaluate the skeletal muscle index (SMI) (8). Since, the patient’s state of consciousness was not suitable, an informed consent was obtained from his relatives before CT examination. Image was obtained to calculate SMI from caudal region of the third lumbar (L3) vertebrae to evaluate the right and left psoas muscle, which was the best determinative area of muscle mass in abdominal CT. Thus, SMI was calculated as a total psoas muscle area divided by height squared (Figure 1). Also, total muscle area (TMA, in cm²) is measured at L3 using a semi-automatic segmentation software (Figure 2). The TMA was then normalized to obtain SMI in cm²/m² (2). The patient’s SMI was found to be 48.6 cm²/m² (cut-off < 52.4 for sarcopenia in male) according to the formula SMI=(skeletal muscle mass/body mass) × 100, which was used by Janssen et al. to define sarcopenia (9). The psoas muscle area (PMA), which was the core muscle that reflects the condition of skeletal muscle in the whole body, was calculated as 12.1 (cut-off <16.8 for sarcopenia) in our patient (10). Low muscle strength and low physical performance could not be evaluated with diagnostic tests for two other criteria of sarcopenia in the patient who was not able to orientate and cooperate. The patient was considered to have low muscle strength and low physical performance because of inadequate respiratory effort and poor mobility of the extremities. In the laboratory analysis hypoalbuminemia (1.8 g/dL) and concurrent CRP (4 mg/L) associated with sarcopenia were normal (to exclude inflammatory causes) (1). Nutritional supplementation (daily caloric intake of 30 kcal/kg, protein intake of 2 g/kg body weight, vitamin D replacement) and exercise program were started for the patient who was diagnosed sarcopenia secondary to infection (11,12). The patient was discharged with tracheostomy with MV support and PEG on the 115th day of hospitalization. The relatives of the patient provided written informed consent before all procedures.
DISCUSSION

Sarcopenia is defined as age-related reduction in skeletal muscle mass. Its incidence is 29% in elderly people and 33% in patients required long-term palliative care. However, its incidence is not clear in ICU (5). The pathophysiology of sarcopenia is multifactorial. Decreased calorie intake, muscle fiber denervation, intracellular oxidative stress, cytokinesis, endocrine and metabolic factors as well as genetic predisposition may cause sarcopenia. Difficulty in weaning of the patients from MV support is associated with prolongation of hospitalization, and acute and chronic weakness of the muscles (1,5).

Nevertheless, the relationship between neuromuscular acquired weakness and secondary sarcopenia is not fully known. In addition, it may not be possible to prevent muscle loss due to increased catabolism in the first period. Although proper protein intake and exercise have been used successfully to treat weakness in older patients (primary sarcopenia), it is possible to fail in severe catabolic status as in our patient, even if standard treatment is applied in sarcopenia due to secondary conditions (5,13). Studies on sarcopenia in patients admitted to the ICU are lacking. Therefore, secondary sarcopenia should be kept in mind for the patients who are cared in the ICU for a long-term period(11). If sarcopenia is overlooked, and not diagnosed and treated early in time, it is associated with increased morbidity and mortality (5,13).

Muscle mass (i), muscle strength (ii) and physical performance (iii) should be evaluated to diagnose sarcopenia based on modern definitions. Screening for sarcopenia is recommended in both elderly patients and patients with significant reduction in physical function (5). The European Working Group on Sarcopenia in Older People (EWGSOP) proposed three stages of sarcopenia: presarcopenia (presence of one criterion), sarcopenia (two criteria), and severe sarcopenia (three criteria) (8). There are some difficulties in assessing ICU patients from a diagnostic standpoint. If patients with sarcopenia are orientated and cooperated enough related to age and disease status, muscle strength and physical performance can be evaluated. As in our patient, central nervous system disease and prolonged respiratory support without sedation and weakness can be considered as indicators of low muscle strength and low physical performance (5,13). Imaging methods used to measure muscle mass are ultrasound (US), MRI, CT, DXA, and BIA. Ultrasonography, DXA and BIA are easy techniques to use for the diagnosis (13). However, the CT and MRI, which are the gold standard methods to evaluate muscle mass of patients in ICU, are difficult to perform and expensive (5). However, it is thought that the patient should be evaluated with CT for a more accurate diagnosis of muscle mass (13). It has been shown that cross sectional muscle surface at the third L3 best reflects total skeletal muscle mass determined by CT or MRI. In practice, TMA is measured at L3 using a semi-automatic segmentation software on a dedicated post-treatment station. TMA is then normalized to stature (using height^2 in m^2) to obtain the SMI in cm^2/m^2 (2,9). The cut-off value of sarcopenia in men is <52.4, while the cut-off value of sarcopenia in women is declared to be <38.5 (1.9). Our patient SMI was found to be 48.6 cm^2/m^2 (for men) according to the SMI. The PMA, which was the core muscle that reflects the condition of skeletal muscle in the whole body, was calculated as 12.1 (cut-off <16.8 for sarcopenia) in our patient (10). The patient who was considered to have sarcopenia based on the diagnostic criteria, should receive proper treatment and exercise. However, despite proper medical treatment, exercise, protein and energy support, MV support and length of hospitalization of the patient were prolonged due to secondary sarcopenia. Therefore, some criteria and tools should be used to assess the morbidity and mortality of critically ill patients during the hospitalization. Once sarcopenia suspected, it should be diagnosed early, and supportive treatment should be started immediately. (14). As in our patient, sepsis is a risk factor for prolonged
ventilator and acquired neuromuscular weakness, which may be a common problem of patients in ICU (15). We aimed to present our case to ensure that secondary sarcopenia should be considered and draw attention to diagnostic difficulties in patients with prolonged ventilation and duration of hospitalization in ICU despite the treatment of primary disease and proper physical therapy, energy and protein support. There is a need for further advanced studies on the frequency of sarcopenia, its progress during the hospitalization, proper nutritional requirement, normal SMI attainment, duration of hospitalization and effect on mortality especially in patients in ICU.
